Summary of the Base Paper and of the Network Estimators

Diebold and Yılmaz (2014) define connectedness through the H-step generalized forecast-error variance decomposition (GFEVD) of an approximating VAR. The share of the forecast-error variance of variable i due to shocks in variable j is read as a weighted, directed link $j \to i$; row sums of the off-diagonal entries give how much each node receives ("from"), column sums how much it transmits ("to"), and the cross-sectional average is total connectedness. Using the generalized decomposition of Koop et al. (1996) and Pesaran and Shin (1998) makes the network invariant to the ordering of the variables. Rolling-window estimates track how connectedness changes over time.

NETS (Barigozzi and Brownlees, 2019) estimates the network directly as a sparse object: a lasso-type estimator of a VAR delivers a *Granger* network (lagged dependence), the sparse concentration matrix of the VAR innovations delivers a *contemporaneous* partial-correlation network, and their combination delivers a *long-run* partial-correlation network.

FNETS (Barigozzi et al., 2024) first removes a (possibly dynamic) common factor structure, estimated by dynamic principal components in a generalized dynamic factor model (Forni et al., 2000), and then estimates a sparse VAR and sparse (long-run) partial correlations for the idiosyncratic component. It therefore separates connectedness due to pervasive common shocks from idiosyncratic, network-type interdependence.

[To be completed: professor's papers on the idiosyncratic component, to be added]

1 Motivation

[To be completed: Why measuring connectedness among emerging equity markets matters (contagion, portfolio diversification, policy spillovers). Argentina is treated as one case among the 17 markets (its final role, decision 6 of paper structure v2, is still to be defined by the group). Suggested anchors from the data: the Argentine primary-election shock of August 2019 (largest weekly ARGT drop, -28.4% log return) and the March 2020 crash.]

2 Introduction

[To be completed: Research question (working version): how does measured connectedness among emerging equity markets change with the estimation method (Diebold–Yilmaz, sparse VAR, NETS, FNETS), and what share of it is a global common factor versus idiosyncratic? State hypotheses and the contribution; summarize the main results once Section 5 is written.]

3 Data

Universe and sample. We use US-listed, USD-denominated country exchange-traded funds (ETFs) as tradable proxies for 17 emerging equity markets: Argentina (ARGT), Chile (ECH), Brazil (EWZ), Mexico (EWW) and Peru (EPU) in Latin America; South Korea (EWY), Taiwan (EWT), India (EPI), China (FXI), Thailand (THD), Indonesia (EIDO), Malaysia (EWM), Vietnam (VNM) and the Philippines (EPHE) in Asia; South Africa (EZA), Turkey (TUR) and Poland (EPOL) in EMEA. The S&P 500 ETF (SPY) is included as a global reference node. Funds were selected if their price history starts by 3 March 2011 (7-day tolerance), at most 5% of weeks are missing, and average daily traded volume is at least USD 3 million. Colombian funds (ICOL, GXG), INDA and MCHI did not pass the criteria; India and China are represented by EPI and FXI. The common sample runs from 11 March 2011 to 23 October 2026, i.e. 816 weeks, with no missing values.

Returns and frequency. Prices are dividend- and split-adjusted, so returns are total returns. We use weekly Friday-to-Friday log returns. The weekly frequency follows the course indication that weekly returns retain some forecastability that is absent at daily frequency; it also mitigates non-synchronous trading between Asian and EMEA local markets and their US-listed ETFs. Unlike Diebold and Yılmaz (2014), who study (realized) volatilities, we study returns: no daily data are available to build realized weekly volatility, and returns are the object of the forecastability argument. Returns are not devoid of cross-market predictive content: in a full-sample VAR(1) on the 18 series, 59 of the 324 slope coefficients (18.2%) are significant at the 5% level, against 5% expected by chance. Our networks therefore describe the transmission of return shocks, not of risk.

Descriptive statistics. Table 1 reports summary statistics. All series are strongly leptokurtic and mostly negatively skewed; an augmented Dickey–Fuller test rejects a unit root for every series. Five weekly log returns exceed 25% in absolute value (ARGT in the week of the August 2019 primary elections and four observations in March 2020); they are genuine market moves and are kept. The March 2020 crash dominates the tails: of the ten largest weekly drops pooled across the 17 emerging markets, eight occur in the weeks ending 13 and 20 March 2020, and 14 of the 17 markets record their worst week in March 2020.

Table 1: Descriptive statistics of weekly log returns, 2011-03-11 to 2026-10-23 (816 weeks). Kurtosis is not in excess.

Ticker	Country	Region	Start	Mean (%)	Std (%)	Min (%)	Max (%)	Skew.	Kurt.
ARGT	Argentina	Latin America	2011-03-11	0.15	4.18	-28.4	24.0	-0.51	8.9

SPY	United States	Global	2011-03-11	0.25	2.23	-15.7	11.4	-0.74	9.3

Limitations. (i) ETF returns embed exchange-rate movements against the USD and are subject to non-synchronous trading. (ii) ARGT changed its underlying index in August 2014 (from a Solactive Argentina index to the MSCI All Argentina 25/50). (iii) FXI tracks only the 50 largest Chinese firms (FTSE China 50) and EPI is the earnings-weighted WisdomTree India fund, so neither is a broad market index. (iv) Colombia is absent. (v) Liquidity requirements and the common start date exclude younger funds. (vi) Without daily data, realized-volatility connectedness cannot be computed.

4 Methods

Let $y_t \in \mathbb{R}^N$ be the vector of weekly returns ($N = 18$). All methods are estimated on rolling windows of $w = 104$ weeks; each estimate is dated at the last week of its window. For the comparison, all methods use the same 179 windows (step of four weeks, first window ending 1 March 2013).

4.1 Diebold–Yilmaz connectedness

We fit a VAR(p), $y_t = c + \sum_{k=1}^{p} A_k y_{t-k} + \varepsilon_t$, $\mathbb{E}[\varepsilon_t \varepsilon_t'] = \Sigma$, by OLS, with $p \in \{1, 2\}$ selected by BIC in each window. The cap $p \leq 2$ is an adaptation: with $N = 18$ and about 100 observations per window, $p = 3$ would mean 55 regressors per equation. With MA coefficients Ψ_h ($\Psi_0 = I$), the H-step generalized variance share (Pesaran and Shin, 1998) is

$$\theta_{ij}(H) = \frac{\sigma_{jj}^{-1} \sum_{h=0}^{H-1} (e_i' \Psi_h \Sigma e_j)^2}{\sum_{h=0}^{H-1} e_i' \Psi_h \Sigma \Psi_h' e_i}, \qquad \tilde{\theta}_{ij} = \theta_{ij} \Big/ \sum_j \theta_{ij}, \tag{1}$$

which is invariant to the ordering of the variables. Following Diebold and Yılmaz (2014), $C_i^{\text{from}} = 100 \sum_{j \neq i} \tilde{\theta}_{ij}$, $C_j^{\text{to}} = 100 \sum_{i \neq j} \tilde{\theta}_{ij}$, net connectedness $C_i^{\text{net}} = C_i^{\text{to}} - C_i^{\text{from}}$, pairwise net $100(\tilde{\theta}_{ji} - \tilde{\theta}_{ij})$, and total connectedness $C = \frac{100}{N} \sum_{i \neq j} \tilde{\theta}_{ij}$. The baseline horizon is $H = 4$ weeks. The base paper uses daily data, 100-day windows and $H = 12$ days; we keep the logic (a horizon of about one month, a window long enough for a stable VAR) on the weekly scale.

4.2 Sparse VAR (lasso)

As a bridge between the dense DY VAR and the sparse network estimators, we estimate each VAR equation by the lasso (Tibshirani, 1996) on lags $1, \ldots, 4$ (standardized regressors, unpenalized intercept), so that the penalty performs lag selection. The penalty is chosen per equation by time-series cross-validation (five expanding folds, test blocks always after the training block; random K-fold would leak future information), over 40 log-spaced values; the extended BIC (Chen and Chen, 2008) is an alternative. The same GFEVD and connectedness measures are computed on the lasso VAR, so differences with DY isolate the effect of regularization.

4.3 NETS

NETS (Barigozzi and Brownlees, 2019) jointly estimates a sparse VAR(1) and a sparse concentration matrix $K = \Sigma^{-1}$ of the innovations by adaptive lasso (Zou, 2006; Peng et al., 2009). Since the `nets` package requires the penalty to be supplied, we select it by BIC over 15 log-spaced values. The Granger network is given by the non-zero entries of A_1, the contemporaneous network by the partial correlations $-K_{ij}/\sqrt{K_{ii}K_{jj}}$, and the long-run network by the partial correlations of $K_{LR} = (I - A(1))' K (I - A(1))$. Each window is standardized before estimation.

4.4 FNETS

FNETS (Barigozzi et al., 2024; Owens et al., 2024) assumes $y_t = \chi_t + \xi_t$, where the common component χ_t is driven by q dynamic factors and the idiosyncratic component ξ_t follows a sparse VAR. We use the unrestricted (generalized dynamic) factor model, select q with the Hallin and Liška (2007) information criterion (criterion IC5, the package default), estimate the idiosyncratic VAR(1) by lasso with the penalty chosen by the package's BIC, and estimate contemporaneous and long-run partial correlations of ξ_t with the package's CLIME-type estimator (Cai et al., 2016) and adaptive thresholding. The share of variance explained by the common component is $\text{var}(\chi_{it})/\text{var}(y_{it})$. Applying the GFEVD to the idiosyncratic VAR yields *idiosyncratic connectedness*; comparing it with DY measures how much connectedness is due to the common factor. With $N = 18$ and $T = 104$ the estimated idiosyncratic innovation covariance is often not positive definite; we project it onto the positive-definite cone by clipping eigenvalues at 1% of the mean absolute eigenvalue, and clip partial correlations to $[-1, 1]$ (the support of the network is unchanged).
